

### **SOIL FERTILITY STATUS AND PRODUCTIVITY OF RICE ON THE FLOOD PLAINS OF WUKARI, TARABA STATE, NIGERIA**

**ABSTRACT:** This work was carried out to determine the soil fertility status and productivity of rice on the flood plain soils at different locations in Wukari LGA of Taraba State in the southern guinea savanna zone of Nigeria. The treatments consisted of five locations (Gidan Idi, Gindin Dorowa, Tsokundi, Rafin Kada and Nwuko) that was laid out in a Randomized Complete Block Design (RCBD) and replicated three times. The land was cleared, ploughed and harrowed, and marked into plots of 5 m x 5 m with an alley of 1 m between replications and 0.5 m between plots. Rice seeds were sown by dibbling at a spacing of about 25 cm x 20 cm intra row. Nitrogen fertilizer was applied at 3 to 4 weeks after planting as urea at the rate of 120 kgN ha<sup>-1</sup> by top dressing method. Phosphorus fertilizer was also applied at 5 to 8 weeks after planting in split doses at the rate of 40 kg P<sub>2</sub>O<sub>5</sub> ha<sup>-1</sup> as single super phosphate and Potassium oxide fertilizer was applied 10 to 12 weeks after planting at the rate of 40 kg K<sub>2</sub>O ha<sup>-1</sup> by top dressing method. Soil and plant data were collected and analyzed using standard procedures. The results obtained were subjected to analysis of variance and means separated using F-LSD test. Significant (P ≤ 0.05) differences were observed for plant height in 2016 and 2017 and grain yield in 2016 but significant (P ≤ 0.05) differences were not observed for all the other parameters measured. Rafin-Kada recorded the highest grain yield of 8.36 tons/ha while Nwuko recorded lowest grain yield of 7.43 tons/ha in 2016. Gidan-Idi recorded the highest grain yield of 8.33 tons/ha while Gindin-Dorowa recorded lowest grain yield of 7.41 tons/ha in 2017.

**KEY WORDS:** Productivity, Flood Plain, Soil Fertility Status, Rice.

#### **1.0 INTRODUCTION**

Flood plain soils are soils adjacent to major rivers or streams. These soils are highly heterogeneous as a result of the hydromorphic environment in which they are formed (Effiong and Ibia, 2009). Flood plain soils as a natural resource can only be properly managed with proper understanding of its characteristics (Idoga *et al.*, 2005). The agricultural productive potentials of river banks and floodplains such as the Nile valley have been identified as the origin of great human civilizations (Carating *et al.*, 2014). Floodplain soils tend to be more fertile than adjoining upland areas and availability of moisture makes them suitable for year-round cropping (Ogban and Babalola, 2009). Despite their potentials, the flood plain soils in Nigeria are largely underdeveloped and underutilized. The complex nature of these soils, arduous agronomic task on management coupled with inadequate information on these soils in Nigeria has contributed to their underutilization (Ukabiala, 2012).

Rice is grown on  $156 \times 10^6$  ha with the production capacity of  $660 \times 10^6$  tons worldwide (Dengiz, 2013). Rice is not only the staple food for nearly half of the world's population as the major daily source of calories and protein, but is also a key source of employment and income for rural people (FAO, 2003). Rice is important in Nigeria for several reasons. It is a major contributor to internal and sub-regional trade. Rice is also the staple for most of the peoples in the Niger-Benue trough which divides Nigeria into three parts, Sokoto-Rima Basin in the north-west, Chad Depression in the north-east, Hadejia-Jamaare trough in the extreme north, and Cross River trough in the south. Farmers find rice more adaptable than a high input staple like maize

when there is declining soil fertility because of the huge array of varieties they can switch over to every year. Since it is becoming a staple crop, farmers seem to be willing to grow it all the time no matter the constraints they are facing.

Crops such as rice, tomatoes, sorrel, amarantus, cabbage, sesame, okra, pepper and onions are largely cultivated under irrigation on the floodplain soils in Nigeria. The floodplain soils potential is high in Taraba State, based on available area for irrigation and free of forest cover and requires no drainage. These areas have potential for irrigation, using underground and surface water; they remain still under-developed thereby limiting significant commercial activities. FAO (1986) indicated that knowledge of the soil within a potential irrigation area is essential for economic and technical reasons. The design of the irrigation scheme itself is dependent on detail knowledge of soils lying within the irrigable floodplain areas. Ojanuga *et al.* (1996) stated that wetland soils are grossly underutilized in Nigeria for any kind of purpose, especially in the drier Guinea, Sudan and Sahel savannas where wetlands are loci for permanent agriculture. This important crop like any other crop requires increased productivity through the use of appropriate variety. The use of local varieties has attracted less attention by farmers due to low yield. Problems of pest and disease were observed affecting the performance of the crop.

Soil productivity is the capacity of a soil in its natural environment to produce a specific plant or sequence of plants under specific systems of management. Efficient management of natural resources is essential for ensuring food supplies and sustainability in agricultural development. The task of meeting demand without affecting the ecological assets for future generations is being given top priority by both scientists and planners. There is an urgent need to match the land resources with the current land use for sustainable production and to meet the needs of society, while conserving fragile ecosystems (FAO, 1993). Therefore, this work was carried out to identify the soil fertility status and productivity of rice on the floodplains of Wukari, Taraba State, Nigeria.

## **2.0 MATERIALS AND METHODS**

### **2.1. Experimental Site.**

The experiment was conducted during 2016 and 2017 dry seasons at Wukari flood plain, Taraba State, North Eastern Nigeria (latitude 7° 51' N and longitude 9° 47' E). The area is sparsely populated, with an estimated population density of 19 to 22 people per km<sup>2</sup>. Agriculture is the most important economic activity in the area, employing more than 90% of the labour force. Most of the farmers are subsistence oriented.

The area received an annual rainfall of 750 to 1600 mm. Rainfall distribution is unimodal, with much of the rain falling between May and October. The wettest months are August and September. The rainy season is followed by a long dry season. The temperature characteristics are typical of the West African savanna climate. Maximum temperature can reach 39°C particularly in April while minimum temperature can be as low as 18°C between December and January. The mean monthly temperature ranges from 26.7°C in the south to 27.8°C in the northeastern part. Humidity is generally lowest in the dry season about 20% and is very high in the wet season about 80% in August. An increase in the humidity always precedes the onset of the rains in May.

The area is richly supplied with a network of river and streams. Rivers Bantaje and Gindin-Dorowa form the major rivers and joined by numerous tributaries. The topography is generally flat, becoming undulating and hilly toward the northeast.

### **2.1 Experimental Treatments and Design**

The land was cleared, ploughed and harrowed. The field was marked into plots of 5 m x 5 m with an alley of 0.5 m between plots and 1.0 m between replications. There were five treatments (locations: Gidan Idi, Gindin Dorowa, Tsokundi, RafinKada and Nwuko) that were replicated three times and laid out in a Randomized Complete Block Design (RCBD). The total land area of the experiment was 230 m<sup>2</sup> in each location.

## **2.2. Land Preparation and Planting**

Early maturing variety, Faro 44 (sipi 6920233) was obtained from the Liaison Office of the Value Chain Development Project Wukari for planting. Prior to sowing, the seeds were soaked in water to determine its viability through floating method. Planting was by direct seeding. Planting depth was 2-4 cm. Dibbling was done at an approximate spacing of 25 cm x 20 cm intra row. Nitrogen fertilizer was applied at 3 to 4 weeks after planting as urea at the rate of 120 kgN ha<sup>-1</sup> by top dressing method. Phosphorus fertilizer was also applied at 5 to 8 weeks after planting in split doses at the rate of 40 kg P<sub>2</sub>O<sub>5</sub> ha<sup>-1</sup> as single super phosphate and Potassium oxide fertilizer was applied 10 to 12 weeks after planting at the rate of 40 kg K<sub>2</sub>O ha<sup>-1</sup> by top dressing method. Manual weeding was done regularly especially during early stages of growth. Harvesting was done when 80-85 % of the grains turned straw colour to avoid shattering (i.e. 4-5 weeks after 50% flowering). The rice stem was cut with sickle at about 15-20 cm above the ground (to permit hand threshing). The panicles were tied in bundles and heaped for drying before threshing. The rice was dried to 12-14% moisture content before threshing.

## **2.1 Soil Sampling and Analysis**

Composite soil samples were collected from the plots before planting and after the planting based on the treatments. The collected samples were used to determine soil physical and chemical properties. Particle size distribution was determined by Bouyoucos hydrometer method of mechanical analysis (Trout *et al.*, 1987). The bulk density was determined by the core Method of known soil volume (Fuller and Warrick, 1985). Available water capacity was determined with pressure plate apparatus as described by Singh *et al.*, (2013). Soil pH was measured electrometrically using glass electrode pH meter in a solid-liquid ratio of 1:2.5 (Hendershot *et al.*, 1993). Total nitrogen was determined by macro-Kjeldahl digestion technique method (Bremner, 1996). Exchangeable bases were determined by the neutral ammonium acetate procedure buffered at pH 7.0 (Thomas, 1982). Exchangeable acidity was determined by a method described by McLean (1982). Organic carbon was analyzed by wet digestion and the organic carbon content was multiplied by 1.724 to get the percentage organic matter (Nelson and Sommers, 1982). Available phosphorous was determined by Bray 1 method according to the procedure of Nelson and Sommers (1982). Cation Exchange Capacity was determined using neutral ammonium acetate leachate method (Summer and Miller, 1996). Base saturation was computed as Total exchangeable bases divided by Cation Exchange Capacity.

## **2.3 Plant Data Collection**

Agronomic data collected includes plant height, leaf area index, and grain yield per hectare and 1000 grain weight.

## **2.4 Statistical Analysis**

The data generated were analyzed statistically using analysis of variance (ANOVA) to check for significant effects of studied parameters at 95% confidence limit using the procedure by Steel

and Torrie (1980). When significant differences were observed, treatment means were separated using F-LSD. The analysis of variance (F-ratio) is a parametric test for significance among three or more variables. In this study, it was used to test for variations in the selected parameters over the different locations at different periods while the F-LSD test was used to test for significant association between pairs of locations or periods. SPSS 17.0 software (SPSS inc., Chikago, IL, USA) was used for the statistical analysis.

### 3.0 RESULTS AND DISCUSSION

#### 3.1 Soil status

The soil from the study area was clay loam in texture (Table 1). Generally, the mean values of the soil textural analysis indicate that the clay fraction dominated the fine earth separate. This was closely followed by the sand fraction, while the silt fraction was the lowest. The soil textures in these areas are mainly clay loam, which is medium texture. Bulk density of the flood plains had lowest mean value of 1.30 g/cm<sup>3</sup> and highest mean value of 1.33 g/cm<sup>3</sup>. These values also agree with Brady (1990) that density of clay loam surface normally ranged from 1.00 to 1.60 g/cm<sup>3</sup>. The bulk density values of the flood plains were lower than 1.6 g/cm<sup>3</sup>, thus rated medium, a range considered adequate not to impede root penetration (Donahue *et al.*, 1990). The lowest value of mean available water capacity recorded in the flood plains is 0.25 m/m while the highest mean value is 0.28 m/m. Generally, the available water capacity of these soils is low.

Table 2 shows the mean soil chemical properties of the flood plain. The soil pH measured in water was neutral to slightly acidic indicating that the pH range is optimum for the cultivation of most crops, but proper management should be maintained in order to reduce the chances of alkalinity hazards. The soils of the flood plains had mean pH values range from 6.47 to 7.05. Soil reaction was slightly acidic to neutral (Malgwi, 2001). The value of the organic carbon content was of moderate class (1.46 to 1.53%) indicating that the soil was moderate in organic matter content. The soils organic matter (OM) contents of the flood plains had highest mean value of 2.65 % and lowest mean value of 2.52 %. Organic matter is generally low in the soils according to Landon (1991) ratings ( >20 % very high, 10-20 % high, 4-10 % medium, 2-4 % low and < 2 % very low). The nitrogen content of the soil was low (0.123 to 0.175%). The available phosphorus content of these soils is high with highest mean value of 18.00 % and lowest mean value of 16.20 %. These high values may be due to the fact that phosphorus is characteristically immobile, and tend to remain fixed at the surface. The exchangeable bases comprised of exchangeable calcium, magnesium, potassium and sodium. Calcium was the dominant exchangeable base in all the soils. The exchangeable calcium (Ca) in the flood plains was rated medium range, the range in value of magnesium were moderate, potassium values were generally in the medium range and sodium values were generally in the medium range. Generally, the exchangeable bases occurred in the order Ca>Mg>K>Na in all the flood plains, this corroborates earlier reports on soils of the Nigerian savannah (Raji, 1995). The exchange acidity comprises exchangeable hydrogen and exchangeable aluminium. The values were classified as generally in the medium range which suggests that the soils have little or no acidity problems, except for incipient acidity in some horizons. The cation exchange capacity of Wukari flood plains were rated medium which agrees with the findings of Adepetu *et al.* (1979) who reported cation exchange capacity values of < 6, 6 - 12 and > 12 cmol(+)/kg as low, medium and high respectively. Base saturation (BS) of the flood plains had highest mean value of 55.90 % and lowest mean value of 53.69 %. The values were rated moderate being generally between 50 and 80%. The medium values indicate that the soils have moderate potentials for supplying plant nutrients; hence, the necessity for adequate soil management, most especially the upland.

### 3.2 Rice Productivity within the Study Locations

The plant growth parameters analyzed are plant height (cm), leaf area indexes at 42 days after planting (LAI at 42 DAP) and leaf area indexes at 63 days after planting (LAI at 63 DAP) while the plant yield parameters analyzed are grain yield per hectare (t/ha) and one thousand (1000) grain weight (g).

#### 3.2.1 Plant height

The results of the plant height from the flood plains showed that Nwuko flood plain had a mean plant height of 89.00 cm in 2016 and 89.84 cm in 2017; Tsokundi flood plain had a mean plant height of 86.877 cm in 2016 and 89.77cm in 2017; Rafin-Kada flood plain had mean plant height of 85.97cm in 2016 and 87.37cm in 2017; Gidan-Idi flood plain had mean plant height of 91.27 cm in 2016 and 98.37 cm in 2017 and Gindin-Dorowa flood plain had mean plant height of 91.17cm in 2016 and 107.07 cm in 2017 (Table, 3.).

The highest mean rice plant height of the flood plains was 107.07cm in 2017 at Gindin Dorowa and the lowest was 85.97ncm in 2016 at Rafin Kada. The ANOVA test confirms the observed variations, in that, the differences amongst the different flood plain locations are statistically significant at 0.05 probability level for both the periods studied. The analysis of means using F-LSD at  $P \leq 0.05$  showed that most of the location means are statistically different.

#### 3.2.2 Leaf area index (LAI)

The results showed that Nwuko flood plain had mean leaf area index at 42 days after planting (DAP) of 4.2 in 2016 and 5.0 in 2017; Tsokundi flood plain had 4.3 in 2016 and 4.0 in 2017; Rafin-Kada had 4.0 in 2016 and 5.7 in 2017; Gidan-Idi flood plain had 4.3 in 2016 and 5.9 in 2017 and Gindin-Dorowa flood plain had mean leaf area indexes at 42 DAP of 4.4 in 2016 and 5.6 in 2017 (Table, 3).

The highest mean leaf area index at 42 DAP of the flood plains was 5.9 at Gidan Idi in 2017 and the lowest was 4.0 in Rafin-Kada in the year 2016. The Analysis of Variance (ANOVA) test confirm the observed variations, in that, the differences amongst the different flood plain locations are statistically not significant at 0.05 probability level for both the periods studied (Table, 3).

The results also indicated that Nwuko flood plain had mean leaf area index (at 63 DAP) of 11.2 in 2016 and 11.5 in 2017; Tsokundi flood plain had 9.3 in 2016 and 10.9 in 2017; Rafin-Kada flood plain had 10.7 in 2016 and 10.4 in 2017; Gidan-Idi flood plain had 9.9 in 2016 and 12.0 in 2017 and Gindin-Dorowa had 11.3 in 2016 and 10.7 in 2017 (Table, 3).

The highest mean leaf area index at 63 (DAP) was 12.0 in 2017 at Gidan-Idi while the lowest was 9.3 in 2016 at Tsokundi. The ANOVA showed that the rice leaf area index at 63 DAPS were not significantly different for the different locations investigated ( $P \leq 0.05$  level of significance) for both periods.

### **3.2.3 Grain yield per hectare**

The results of the grain yield from Nwuko flood plain was of 7.42 t/ha in 2016 and 7.82 t/ha in 2017; Tsokundi flood plain had mean grain yield of 8.33 t/ha in 2016 and 7.84 t/ha in 2017; Rafin-Kada flood plain had 7.36 t/ha in 2016 and 8.02 t/ha in 2017; Gidan-Idi had 8.00 t/ha in 2016 and 8.33 t/ha in 2017 while Gindin-Dorowa had mean grain yields of 7.92 t/ha in 2016 and 7.4 t/ha in 2017 (Table, 3).

The highest mean rice grain yield of the flood plains was 8.36 t/ha obtained from Rafin-kada in 2016 and the lowest mean rice grain yield of the flood plains was 7.41 t/ha obtained from Gidan-Idi in 2017. The ANOVA showed that rice grain yield of the floodplains were significantly different for the different locations investigated ( $P \leq 0.05$  level of significance) in 2016 but were not significantly different for the different locations ( $P \leq 0.05$  level of significance) in 2017. The means separation using F-LSD at 0.05 probability level showed that the differences among some of the mean rice grain yield of the floodplain locations are statistically significant.

### **3.2.4 Thousand (1000) grain weight**

The results of the 1000 grain weight showed that Nwuko flood plain had 6.95 g in 2016 and 27.42 g in 2017; Tsokundi had mean thousand (1000) grain weights of 26.53 g in 2016 and 26.95 g in 2017; Rafin-Kada had 25.80 g in 2016 and 26.78 g in 2017; Gidan-Idi had 27.08 g in 2016 and 27.39 g in 2017 and Gindin-Dorowa had 26.92 g in 2016 and 26.78 g in 2017 (Table, 3).

The highest mean one thousand (1000) grain weight of rice was 27.42 g at Nwuko and the lowest was 25.80 g at Rafin-kada. The ANOVA showed that the one thousand (1000) grain weights were not significantly different for the different locations investigated ( $P \leq 0.05$  level of significance) for both periods of study.

## **4.0 Conclusion and Recommendations**

The soils of Wukari Floodplains are mostly clay loam in texture having very slightly acid to neutral soil reaction, moderate organic matter, low total N, available P, exchangeable bases and CEC. This indicates that if adequate soil management practices are not employed, these soils will deteriorate and may not support sustainable crop production.

The flood plain soils were moderate in fertility, a confirmation of the general characteristics of Savanna soils reported by earlier researchers. There were significant variations among the flood plain soils at the different locations. They are highly to marginally suitable for rice production based on the quantitative method as this method considered permanent factors which are not easily changed. It has implication on land productivity of Wukari to meet food and fiber demand of the growing population. This study had revealed the possible sodicity status of the soils of the area and there is need for their proper management. It also revealed information on the limitation of the soils for sustainable rice production. The study also implies that low input was responsible for low outputs recorded by most farmers in the study area.

## Recommendations.

On the basis of this study, the following recommendations are made;

Measures such as the return of crop residues and organic manure addition, minimization of tillage operation, introduction of viable crop rotation techniques and judicious application of chemical fertilizers must be adopted to sustain the fertility and continued productivity of these soils. The water sources used for irrigating the floodplains are relatively safe hence little or no treatment for soluble salts is required.
